Introduction

The World Health Organization (WHO) describes antimicrobial resistance in human pathogens as a global health challenge.1 In the context of food handlers, although human colonization with bacteria such as *s. aureus* is associated high risk to transfer the infection to others, or contaminate foods and food surfaces during handling, information regarding bacteria bioburden is still scarce.2

Considering that *s. aureus* is a cause of staphylococcal food poisoning (SFP), result from ingestion of staphylococcal enterotoxins present in food, is one of the most prevalent foodborne intoxications in the world, with fatality rates particularly concerning for children and the elderly and that foodstuff contamination by colonized food handlers represent a major risk for SFP, the assessment of colonization of these workers is crucial.3 4

Aim of Study

Considering that food contamination by colonized food handlers represent a major risk for SFP, here we aim to assess *s. aureus* colonization prevalence of both sensible and resistant strains in a bakery as a case study.

Materials and Methods

Study Population and Sample

The study included workers from a bakery analysed for occupational-associated colonization of *s. aureus* sensible and resistant to methicillin. The individuals enrolled in the study also answered to a questionnaire for collection of demographic data, daily occupational activity and duration (years), availableness of individual protection equipment at the workplace and daily regular and/or persistent cough episodes Bakery workers enrolled in the study.

Collection, isolation and microbiological procedures

Biological samples were obtained through nasopharyngeal swab procedure using collection swabs with Stuart media. In the microbiology laboratory, samples were cultured in flat petri dishes containing Columbia agar with 5% sheep blood, and incubated for 24 hours at 37°C.

Identification of *s. aureus* was performed in isolated colonies trough catalase test and Slidex Staph Kit (REF). MRSA strains were identified through isolation of the strains in chromID® MRSA agar (Sigma ref# 90923) and confirmed by Slidex MRSA detection Test Kit (Biomerieux ref #73117).

Discussion

1. In the presented case study, we reported a 40% prevalence of *s. aureus* asymptomatic carriers in food handlers, which is higher than levels detected in the community3.1

2. Additionally, our data revealed elevated prevalence of MRSA (10% in bakery workers in comparison to 2%-3% in the community) which is particularly concerning considering that community-associated methicillin resistant strains have also been associated with toxic shock syndrome cases.5

3. Relevantly, the fact that one of the asymptomatic carriers of MSSA was the worker who assumed to have regular and persistent cough occurrences, the probability of spread of this microorganism trough bioaerosols is higher.

4. It is also important to notice that, the identification of proteus spp., a gram-negative bacteria found in human intestine and feces, commonly responsible for urinary and septic infections, often nosocomial, may indicate poor hygiene although colonization has been found in pig-exposed individuals.6

Conclusions

The assessment of *staphylococcus aureus* colonization in food handler personnel such as bakery workers is of foremost importance to evaluate potential sources of food contamination by these microorganisms. This work raises awareness to the necessity of creating valuable occupational health surveillance programs and proper procedures to avoid the occurrence of staphylococcal food poisoning.
